Abstract

Most people are aware that tobacco causes cancer, heart disease, chronic obstructive pulmonary disease, and major health problems, leading to high morbidity and mortality; however, many are not aware of its ill effects on the reproductive health of men and women as well as their children. This article has summarized the current research evidence from literature search to date, including prevalence of tobacco use, types of tobacco use, its effects on male and female fertility, pregnancy and their progeny in utero, neonatal period, childhood, adolescence, and subsequent well-being, with both active and passive smoking and smokeless tobacco use. Although antitobacco campaigns show horrifying visuals linked to tobacco use, not much progress has been made in controlling its use. Publicizing these harmful effects on pregnancy and progeny, making public aware, screening women coming for infertility or antenatal care on any form of tobacco use, and helping them to quit tobacco use may help the National Tobacco Control program, as parents are more concerned if they learn that there is harm to their fertility and progeny. Indirectly, it will help to improve reproductive, maternal, neonatal, child, and adolescent health.

Introduction

Globally, rates of smoking and tobacco use among women are increasing, whereas smoking rates in men show a slow decline. The use of tobacco in middle- and low-income countries is rising and is usually linked to low-income and low-educational status. India is increasingly facing a double burden of disease, and the burden attributed to noncommunicable diseases (NCDs) is growing. Tobacco use is identified as a major NCD behavioral risk factor contributing to several chronic diseases, including cancer, lung diseases, and cardiovascular diseases. India, along with other countries, has endorsed the target of a 25% reduction in premature mortality from NCDs by 2025, and 30% reduction in tobacco use will significantly contribute to achieve this goal.

The use of tobacco in any form, including exposure to second-hand smoke (SHS), adversely affects the functioning of most organ systems of our body. Tobacco use has harmful effects on women through all stages of their lives, starting from childhood through adolescence and reproductive life, extending even into the postmenopausal decades. Most people are aware of the ill effects of tobacco such as respiratory, coronary, and vascular disease, chronic obstructive lung disease, and several types of cancers. However, the adverse effects on reproductive health including increased risk of fetal loss and higher incidence of preterm and low birth babies are rarely publicized. This article reviews the ill effects of smoking and tobacco use in the context of the Government of India Reproductive, Maternal, Newborn, Child Health, and Adolescent (RMNCHA) program.

Materials and Methods

A literature search was performed in PubMed and Medline using key terms such as “tobacco use,” “smoking and reproductive health,” “tobacco and pregnancy,” “tobacco and
neonatal outcome,” “exposure to passive smoking during pregnancy,” “tobacco and child and adolescent health.” All research articles, observational and epidemiological studies, systematic reviews, and meta-analyses focusing on the ill effects of tobacco use in any form on reproductive health have been reviewed, and the observations have been categorized into specific areas to enable the reader to have a comprehensive overview of this issue. As research in this field is limited and a vast range of reproductive health issues have been covered, it is not possible to carry out a systematic review. All relevant literature published on this issue has been analyzed.

Results

There are several epidemiological studies published on the ill effects of tobacco use on reproductive health from several countries including India. Besides, some systematic reviews and prospective cohort studies have also evaluated the effect on pregnancy and its outcome. Few research papers have analyzed the adverse effects of tobacco at a molecular level. After reviewing epidemiology of tobacco use and forms of tobacco use globally and in India, the results have been categorized under specific subheadings, focusing on the ill effects on the reproductive health of women with fertility issues, influence on pregnancy and its outcome, problems in neonates, infants, children, and adolescents, and well-being during adult life due to direct and indirect tobacco exposure in utero.

Epidemiology of Tobacco Use in Women

Despite the evidence of the negative effects of tobacco use, the centers for Disease Control and Prevention (CDC) in the United States reports that 18% of women older than 18 years smoked cigarettes in 2009. This rate of smoking has remained largely unchanged over the past 5 years, thus falling short of the Healthy People 2010 goal of a smoking rate of 12% or less. More than 80% of “current” smokers start before age 18, and lower levels of education and economically backwardness increase the prevalence of tobacco use in women.

There is a paucity of epidemiological data on women in developing countries. Nonetheless, numerous surveys worldwide and in India show a greater prevalence of tobacco use among the less educated and illiterate. In a large population-based study in Mumbai, the odds ratios (ORs) for any kind of tobacco use among the illiterate as compared with the college-educated were 7.4 for males and 20.3 for females after adjusting for age and occupation. Overall, school drop-outs are more likely to take to tobacco use in childhood and adolescence.

As per the Global Adult Tobacco Survey (GATS), India, 2010, India has alarmingly high rates of tobacco consumption. Almost 275 million Indian adults, nearly 35% of the population, consume some form of tobacco. The key findings of GATS highlight that 20.3% of adult women use tobacco products and more than 90% women tobacco users consume smokeless tobacco (a large number of these users are in the reproductive age group). The average age at initiation of tobacco use was 17.8 years, with 25.8% of females starting tobacco use before the age of 15 years. Besides the use of smokeless tobacco, exposure to passive smoking is very common in India. Currently, the tobacco industry is trying to target and attract women aggressively into tobacco use by projecting smoking as something modern and fashionable. Even antitobacco lobbies give a lot of emphasis on curbing tobacco use for preventing lung and oral cancer, and very little attention is being paid to its ill effects on reproductive health women and their progenies.

Different Forms of Tobacco Use

The most common form of tobacco addiction is smoking. Cigarettes are very popular and a glamorized form of tobacco use in most countries including India. Hand-rolled “bidis” are also popular among women of our country, especially those who are illiterate with low socioeconomic status. In recent years, tobacco products have changed, and several others have been developed or are gaining popularity. There are many flavors of cigarettes, cigars, and other forms of tobacco that are available for sale. Menthol cigarettes increase the likelihood and degree of nicotine addiction in new smokers and make smoking cessation more difficult. The more recent forms of smoking alternatives include a gel strip impregnated with nicotine that melts on the tongue and an electronic or e-cigarette, a battery-powered device that heats cartridges of liquid containing nicotine to create a mist, which users inhale.

Smokeless tobacco products are mistakenly believed to be a safer and may be a more convenient alternative to cigarettes where smoking is prohibited. In India, various forms of chewing tobacco products and common forms of smokeless tobacco use are paan with tobacco, bajjar, gudhaku, mishri, and laldantmanjan and creamy snuff used as dentifrice for cleaning teeth. One form of smokeless tobacco popular with young women is “snus,” a flavored self-contained tobacco pouch that is placed between the cheek and gum and does not require spitting.

Use of oral snuff and smoking tobacco with a water pipe (hookahs and chillim) are some other forms of tobacco use seen among the rural Indians. Hookahs, or tobacco water pipes, are popular among youth or young adults. When using a hookah, inhalation is usually deeper and smoking sessions are longer than with a typical cigarette. This leads to higher concentration of toxins after hookah smoking compared with cigarette smoking.

Many Indian women are also involved in tobacco farming or “bidis” rolling. Additionally, there may be others who are employed in cigarette manufacturing companies. These are examples of occupational exposure to tobacco. Most modern cities have too many vehicles on road emitting smoke. The air pollution is yet another manner in which women can be exposed to health hazards.

“Passive smoking” or exposure to SHS is another way a woman may be at risk even when she herself does not smoke, as husband or other relatives smoke in her vicinity, with some of them heavily.
Ill Effects of Tobacco Use on Reproductive Health

Tobacco smoking has a negative influence on female (as well as male) fertility and is even known to cause health issues for postmenopausal women, such as osteoporosis.

Smoking and Fertility

It is clearly established that smoking can have a negative impact on female fertility. Women who smoke take longer to conceive than women who do not smoke. The greater the quantity of cigarette smoked, the longer a woman is likely to take to achieve pregnancy. It is suggested that tobacco consumption affects uterine receptivity; this effect is more likely with heavy smokers. Interestingly, even comparatively low levels of smoking do seem to have a significant impact on female fertility. There is also a higher rate of ectopic pregnancies in smokers.

There is evidence to suggest that smoking reduces the success rate of fertility treatment. Women undergoing assisted reproductive technology (ART) treatment demonstrate a significant negative effect associated with smoking. In a study evaluating 200 in vitro fertilization (IVF)/intracytoplasmic sperm injection cycles, the endometrial thickness in smoking patients was significantly less than nonsmoking patients.

There have been reports of substantial reduction (nearly 50%) in implantation rates among smokers compared with nonsmokers. A study involving IVF cycles with oocyte donors showed that ovarian response was significantly reduced in donors who smoked. However, the oocyte quality, pregnancy rate, and live birth rates were not affected by smoking. A dysregulation of reproductive and hormonal systems caused by maternal smoking reduces the probability of pregnancy in both healthy women and those undergoing ART treatment.

Smoking in men results in erectile dysfunction, lower sperm quality, and decreased testosterone levels, thus lowering the chances of pregnancy. Some of the early reports suggest that smoking during pregnancy has an impact on protamine, a protein essential in sperm production that can lead to fertility problems. Men who smoke have lower sperm count, higher proportion of malformed sperms, and reduced sperm motility. A meta-analysis of studies published since 1980 found that 40 to 80% of current smokers were impotent compared with 28% men in general population.

Furthermore, a growing body of research suggests that maternal smoking may have a negative impact on the fertility of both female and male offspring. Smoking during pregnancy reduces the number of germ cells and somatic cells that form in the developing fetus.

Ill Effects on Maternal Health

Smoking during Pregnancy

In the United Kingdom, by March 2012, the proportion of women smoking at the time of delivery was 13%. This equates to approximately 83,000 infants born to smoking mothers each year. The 2010 Infant Feeding Survey also reports that nearly 26% of mothers smoked in the 12 months before or during their pregnancy. These figures are down from 33% in 2005. Nearly one (54%) of two women who smoked before pregnancy managed to stop once they became pregnant. But sadly, 12% (one out of eight) mothers-to-be continued to smoke throughout their pregnancy. U.S. data from 27 states by the Pregnancy Risk Assessment and Monitoring System shows that ~10.7% of women reported smoking during the last 3 months of pregnancy; however, of women who smoked 3 months before pregnancy, 54% (one out of two) quit during pregnancy, though 44% relapsed to smoking again within 6 months after delivery.

In contrast, a significant fall was noticed in England, with only 14% of mothers reporting to be smoking at delivery in England in 2010. Smoking rates, though, vary significantly throughout the United Kingdom. Those who were young (under the age of 20 years) at the time of conception were significantly more likely to smoke before or during pregnancy compared with older mothers (over the age of 35 years).

Studies have shown that during pregnancy, women consciously reduce the use of tobacco products, alcohol, and caffeine, though it may not make significant changes in their lifestyle or dietary pattern.

In an editorial published in the Indian Journal of Medical Research, it has been reported that Indian women generally do not smoke, though the situation may differ from state to state. In India, reproductive health services do not address tobacco problem at all. But, the prevalence of smokeless tobacco use among women in India is quite high and recent data show that smokeless tobacco use during pregnancy causes nearly the same adverse impact as tobacco smoking. A recent survey has shown that 23% women were exposed to SHS and 6.1% smoked during pregnancy.

Adverse Impact on Pregnancy

According to a CDC report, the health hazards of smoking during pregnancy include more likelihood of having a miscarriage or an abortion, problems with the placenta including placental abruption or placenta previa, prematurity and growth restriction in baby, stillbirth or longer stay in the hospital, risk of sudden infant death syndrome (SIDS or cot death), and certain birth defects such as a cleft lip or cleft palate. There is a recent report evaluating the effect of smoke extract on placental macrophage function, which may be responsible for the adverse pregnancy outcome.

Miscarriage

Miscarriage is usually due to genetic defects induced by nicotine. Smoking may also alter the endometrium, making it more difficult for implantation to take place. There is some evidence that a father who smokes in excess of 20 cigarettes per day may increase the chances of miscarriage because his sperm may get damaged. Some studies indicate that men who smoke have a higher incidence of chromosomal abnormalities in their sperm. Besides, exposure to SHS increases the abortion risk in mother.

A meta-analysis and a 2014 systematic review has reported an increased risk of miscarriage in active smokers, with risk increasing proportionately to the number of cigarettes smoked. Early pregnancy loss is higher in women who...

Fetal Growth Restriction and Low Birth Weight
Maternal smoking is a major risk factor for low birth weight and small for...gestational age babies. Swedish researchers have shown that babies born to women who smoke throughout their pregnancy are on average 162 to 226 g lighter than babies born to nonsmoking mothers. This was also documented in research performed in Spain. Another study reported that maternal smoking could be an independent risk factor in nearly 30% of growth-restricted neonates. Researchers have documented that smoking during pregnancy leads to smaller head circumference and slower growth of the fetal head.

Preterm Births
Recent research in Sweden examined the relationship between maternal smoking and preterm birth. It was found that compared with nonsmokers, moderate smokers had a twofold increase in risk of preterm labor; this risk increases to two and a half times among heavy smokers. An experimental study of amnion exposed to cigarette smoke condensate has shown alteration in the retinoid pathway in amnion-derived epithelial cells. These play a significant role in pathophysiology of membrane rupture and preterm birth. Mouse exposed to e-cigarette smoke have shown altered DNA methylation and lung cytokine expression in their offspring, similar to mechanisms described for preterm birth.

Congenital Malformations
There is an increased risk of congenital defects in the offspring of smokers. The most commonly reported birth defects include orofacial clefts (cleft lip or cleft palate), neural tube defects (defects of the defects of the brain, spine, or spinal cord), cardiovascular/heart defects, musculoskeletal defects, limb reduction defects, missing/extra digits, clubfoot, craniosynostosis (fused skull bones that may affect brain growth), facial defects, eye defects, gastrointestinal defects, gastrochisis, anal atresia, hernia, and undescended testes.

A meta-analysis of 23 articles showed a higher risk of neural tube defects in neonates when mothers smoked (OR: 1.05), and this further increased with exposure to passive smoking. Evaluation of cryptorchidism in Down’s syndrome has shown that 55% of these were children of mothers who smoked during pregnancy. Prevalence of cryptorchidism increased 3.89 times in children exposed to paternal smoke.

Adverse Effects on Neonatal Health
Tobacco use during pregnancy not only harms in utero development of fetus but also continues to have adverse effects on neonate, infant, child and adolescents. Some of these in utero exposed babies continue to manifest some problems even during adult life.

Perinatal Mortality and Sudden Infant Death Syndrome
It is estimated that about one-third of all perinatal deaths including stillbirths and early neonatal deaths in the United Kingdom are caused by maternal smoking. Evidence has demonstrated that babies born to women who smoke during pregnancy are around 40% more likely to die within the first 4 weeks of life than babies born to nonsmokers. A meta-analysis of risk factors in 886,505 women from nine states of India showed that tobacco chewing women had higher odds of having stillbirth (OR: 1.1; 95% confidence interval [CI]: 1.02–1.21) after excluding other confounding factors. Lessons learned from epidemiological and experimental animal model studies confirm these observations.

More than one-quarter of the risk of death due to SIDS is attributable to smoking during pregnancy and exposure to SHS, particularly in the home. McDonnell-Naughton et al report that the risk of cot death has trebled in infants whose mothers smoke both during and after pregnancy. Postnatal parental smoking is cited as an important risk factor for SIDS. Indeed, the greater the number of cigarettes smoked, the higher the risk of SIDS. It is likely that nicotine from tobacco smoke (including its derivatives) easily reach the cerebrospinal fluid in the fetus to cause ependymal damage (the lining providing a protective barrier and filtration system separating the brain from cerebrospinal fluid). The best way to reduce the risk of SIDS or cot death is to maintain a smoke-free home and vehicle at all times.

Smoking and Breastfeeding
Longer periods of abstinence from smoking are linked to better initiation of breastfeeding. Women who have quit smoking for at least a month are more likely to initiate breastfeeding. Additionally, women who quit smoking tend to continue breastfeeding for a longer period of time than those who continue to smoke. Indeed, breastfeeding is still recommended by the National Health Service and the American Academy of Pediatrics, among others, because of its beneficial effects on the baby, even if the mother continues to smoke. It is important therefore that the health care professionals combine smoking cessation and relapse-prevention advice with lactation counseling in women who smoke to maximize success of smokers’ efforts to initiate breastfeeding.

Adverse Effects on Child Health
Effects on Childhood Growth Development and Behavior
One study found that maternal smoking during pregnancy is linked to high fetal testosterone. This leads to an increased risk of autism, childhood attention deficit/hyperactivity disorder (ADHD), conduct disorder, and antisocial behavior. Numerous other studies have demonstrated a link between maternal smoking and ADHD. Data from a recent study also incriminate SHS in causing ADHD.

A population-level study of Finnish children documented that the risk of psychiatric morbidity was significantly
higher among children of mothers who smoked during pregnancy. Studies have found that smoking during pregnancy and exposure to SHS in early childhood were “quite strong” predictors of conduct problems, antisocial behavior, and crime later in life. This finding is supported by other studies exploring the relationship between maternal smoking during pregnancy and behavior problems in childhood and adolescence, including smoking (particularly among girls) and other substance use.

Maternal smoking has been associated with an increased risk of learning difficulties. Prenatal exposure to environmental tobacco smoke in Chinese children has been associated with hyperactive behavior (OR: 1.51) compared with those born to nonexposed mothers. A meta-analysis of offspring with prenatal exposure to maternal smoking has shown a significant association with childhood ADHD. Pre- and postnatal exposure to tobacco results in higher sleep problems in girls at 3 years of age.

In an evaluation of scholastic achievements of offspring of mothers who smoked during pregnancy, childhood in 4th, 7th and 10th grade revealed 5 to 7% lower score compared with children of nonsmoking mothers after controlling for other factors affecting childhood performance.

Ill Effects on Child Health
There is some evidence to suggest that pre- and postnatal SHS contributes to insulin resistance in children. There is strong evidence that childhood obesity can be related to smoking during pregnancy. Two meta-analyses of 7 and 14 studies, respectively, found that for children of mothers who smoked during pregnancy, there was a 47 to 50% increase in the odds of being overweight in childhood.

A meta-analysis of 11 articles analyzing 4,833 children with strabismus concluded that antenatal smoking during pregnancy is significantly associated with strabismus in offspring (OR: 1.46; 95% CI: 1.32–1.60) when mother smoked less than 10 cigarettes per day and increased further (OR: 1.79; 95% CI: 1.39–2.31) if she smoked more than 10 cigarettes per day.

A meta-analysis evaluating 14 case–control studies involving 3,114 children with neuroblastoma showed an association with tobacco use during pregnancy (OR: 1.22).

Adverse Effects on Adolescent Health
Adolescent Health Risks
Prenatal multidrug exposure including tobacco has been correlated with adolescent cognition and attention disorders and with higher rates of substance abuse. An analysis of seven databases evaluating prenatal tobacco exposure and puberty timing observed that it decreases the age of menarche in girls. Gestational tobacco exposure has also been associated with adolescent tobacco dependence and higher use of e-cigarettes.

Late Manifestations in Adult Life
Both maternal smoking and paternal smoking have been associated with low sperm counts in the sons. Sons of smoking fathers have 51% lower sperm count.

It is reported that exposure to cigarette smoke in early fetal development can result in certain epigenetic changes in the lungs of the offspring. These can then be transferred to following generations, resulting in adult onset of respiratory disease. There is some evidence of an association between maternal smoking, early childhood exposure to SHS, and the development of emphysema in adulthood. The preceding findings suggest that the lungs may not recover completely from the effects of early life exposure, even when the offspring continues to be nonsmoker in adult life.

Perinatal exposure to environmental tobacco smoke has been associated with altered DNA methylation in mice. This epigenetic finding could represent a potential biomarker for adult respiratory disease. Another experiment exposing mice to e-cigarettes has shown altered DNA methylation and lung cytokine expression in their offspring. This may be responsible for pulmonary dysfunction at a later age.

Several researchers have also found that adults exposed to tobacco smoke in utero had a more adverse cardiovascular disease risk profile. Some evidence suggests that prenatal exposure to tobacco smoke may be associated with benign breast disease later in life.

Passive Smoking and Pregnancy
Passive smoking is perhaps more relevant to Indian setting as the number of women smoking while pregnant is far less, with high exposure to SHS. However, SHS is associated with similar maternal and fetal risks as is active smoking. SHS exposure during pregnancy has been correlated with lower quality of life and higher incidence of postpartum depression in women, besides its ill effects already discussed. According to a report from U.S. Surgeon General, second-hand tobacco smoke is a mixture of at least 4,000 chemical compounds, many of which are likely to be reproductive toxins. Nonsmoking women exposed to other people’s tobacco smoke during pregnancy are more likely to have lower weight babies.

Several other researchers have reported that nonsmoking women who are exposed to SHS are at an increased risk of infertility or have difficulty becoming pregnant, giving birth prematurely of stillbirth, spontaneous abortion, and having a baby with congenital malformations. Additionally, some evidence suggests that female fertility can be damaged in utero if the woman’s mother was exposed to SHS while pregnancy.

Exposure to SHS can also be damaging in terms of successful pregnancy outcomes for women undergoing IVF or other ART treatment. ADHD has also been linked to SHS exposure in the home, in addition to maternal smoking during pregnancy. Exposure to parental SHS in the home and vehicle is strongly associated with middle ear disease in children. There is some evidence to suggest that prenatal and postnatal SHS may cause leukemia, especially acute lymphoblastic leukemia.

It must be appreciated that research on the reproductive effects of SHS exposure is relatively new compared with that on the effects of active smoking. More epidemiologic research is likely to reveal additional negative health effects, as well as the mechanisms whereby they occur and the dose–response relationships involved.
Smoking and Oral Contraception

It is generally known that women using combined oral contraceptives are at an increased risk of heart disease. However, since the risk of heart disease in young women is low, the benefits of using the pill generally outweigh the risks for young women who do not smoke. This is not the same with women who smoke. In addition, pill users who smoke are also at a risk of venous thromboembolism and arterial thrombosis.\textsuperscript{117,119} It is, therefore, important that all women who take the contraceptive pill be counseled against smoking and advised on the use of alternative method of contraception.

Smoking and Menopause

Women who smoke seem to attain menopause at an early age,\textsuperscript{120} with the natural menopause occurring up to 2 years earlier in smokers. The likelihood of earlier menopause is related to the number of cigarettes smoked; those smoking more than 10 cigarettes a day have an increased risk of early menopause.\textsuperscript{121} It must be emphasized that stopping smoking may lower the risk of early menopause. Research suggests that polycyclic aromatic hydrocarbons found in tobacco smoke can trigger premature egg cell death, which may, in turn, lead to earlier menopause.\textsuperscript{122} Another study suggests that chemicals in tobacco smoke alter endocrine function, which, in turn, affects the release of pituitary hormones. This endocrine disruption is thought to contribute to adverse outcomes, including earlier menopause.\textsuperscript{123}

Postmenopausal women who smoke have lower bone density than women who never smoked. Women who smoke have an increased risk of hip fracture compared with never smokers. Cigarette smoking also causes skin wrinkling that could make smokers appearance less attractive and prematurely old.

Conclusion

Smoking (or tobacco) seems to adversely impact the health of women in all stages of their life, starting from birth to senescence. There is a growing body of evidence that smoking causes “preventable” harm to women’s health, with the ill effects being most profound during pregnancy and immediate puerperium.

The adverse impact of smoking is linked to the number of years of smoking and number of cigarettes smoked each day, and when done during pregnancy, it has a far-reaching adverse impact on the health of her progeny. In India, passive smoking or SHS is also very important.

Knowing the profound ill effects of tobacco, it is worth spending large sums of money on helping people stay away from tobacco addiction. Smoking cessation is possible with the right support and help from health care professionals along with government agencies and self-help groups. Pregnancy and childbirth provide the best opportunity when women are most likely to be motivated to quit smoking (for the sake of the child). By dissuading people from the use of tobacco (in any form), we can prevent several illnesses and substantially reduce the overall disease burden. This translates into better health and improved quality of life for our citizens and would lead to huge savings in government expenditure. Thus, screening for smoking and tobacco use and measures to stop should be integral components of the RMNCHA program in India. Tobacco cessation training needs to be imparted to the care providers, and there is a need to discuss the synergistic role of tobacco control with the basic goal of reducing maternal and child mortality.

In light of the serious health consequences and the strong motivation of pregnant women to ensure the health of their newborns, efforts to help pregnant women quit smoking (and to prevent postpartum relapse) should be accorded a high priority in public health programs focusing on women and children. A mechanism needs to be developed to integrate tobacco control prevalence indicators and cessation advice in the health care delivery system for women.

Conflict of Interest

None declared.

Acknowledgments

A national consultation on tobacco use and its implications on the health of women and their children was organized by the author at Fortis Memorial Research Institute in collaboration with World Health Organization, Ministry of Health and Family Welfare (Government of India), and Indian Council of Medical Research on World No Tobacco Day in 2013. The author is grateful to all the resource persons who participated in the consultation.
